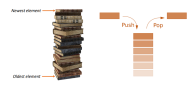
LINEAR STRUCTURES

-- heterogeneous --

STACK (LIFO)

LIFO => Last In, First Out



Operation	Stack content	Returned value
s = Stack()	[]	
s.isEmpty()	[]	True
s.push(2)	[2]	
s.push('hello')	[2, 'hello']	
s.push(5.4)	[2, 'hello', 5.4]	
s.size()	[2, 'hello', 5.4]	3
s.peek()	[2, 'hello', 5.4]	5.4
s.pop()	[2, 'hello']	5.4

Note as peek() return the top element but does not modify the stack

QUEUE (FIFO)

FIFO => First In, First Out

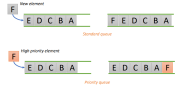
Example

Operation	Queue content	Returned value
q = Queue()	[]	
q.isEmpty()	[]	True
q.enqueue(2)	[2]	
q.enqueue('hello')	['hello', 2]	
q.enqueue(5.4)	[5.4, 'hello', 2]	
q.size()	[5.4, 'hello', 2]	3
q.dequeue()	[5.4, 'hello']	2
q.isEmpty()	[5.4, 'hello']	False

PRITORITY QUEUE

Particular kind of queue. **Each element of the queue has a priority** and the position of the element in the queue depends by its priority.

Highest priority => removed first



DEQUE (double-ended queue)

A double-endend queue where **items can be added and removed at either the front or the rear**. Hybrid between a stack and a queue

Operation	Deque content	Returned value
d = Deque()	[]	
d.isEmpty()	[]	True
d.addRear(2)	[2]	
d.addRear('hello')	['hello', 2]	
d.addFront(5.4)	['hello', 2, 5.4]	
d.size()	[5.4, 'hello', 2]	3
d.removeFront()	[5.4, 'hello']	2
d.removeRear()	['hello']	5.4

-- homogeneous (array) --

Average computational complexity for common operations

Operation	Unordered linked list	Ordered linked list	Python list
isEmpty()	O(1)	O(1)	O(1)
Size()	O(n)	O(n)	O(1)
Add(Item)	O(1)	O(n)	O(1)
Remove(Item)	O(n)	O(n)	O(n)
Search(Item)	O(n)	O(n)	O(n)

LIST (numpy)

Collection of items where each item holds a relative position wrt the others.
Head: first item of the list
End/tail: last item of the list

Ordered list

Operation	What
OrderedList()	Creates a new empty ordered list
add(item)	Adds a new item to the list making sure that the order is preserved
remove(item)	Removes the item from the list
pop()	Removes and returns the last item in the list
pop(pos)	Removes and returns the item at position pos
search(item)	Returns True if the item is present, False otherwise
index(item)	Return the position of the item in the list
isEmpty()	Returns True if the deque is empty, False otherwise
size()	Return to the number of items in the deque

Each item holds a relative position that is based upon some underlying characteristic of the item

Unordered list

Operation	What
init()	Create a new empty list
add(item)	Adds a new item to the list
append(item)	Adds a new item to the end of the list
insert(pos, item)	Add a new item to the list at position pos
remove(item)	Remove the item from the list
pop()	Removes and returns the last item in the list
pop(pos)	Removes and returns the item at position pos
search(item)	Returns True if the item is present, False otherwise
index(item)	Return the position of the item in the list
isEmpty()	Returns True if the deque is empty, False otherwise
size()	Returns the number of items in the deque

LINKED LIST

Unordered list

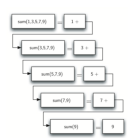
Each element is connected to the next one until the last item. Must maintain **relative position** of the items (no need of contiguous memory positioning)

Insert one element at the end of the list => **O(n)**
Insert one element at the beginning of the list => **O(1)**

RECURSION and DYNAMIC PROGRAMMING

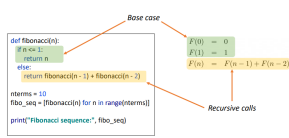
-- recursion --

Problem solving method: breaking a problem in smaller and smaller subproblems until you get enough problem that it can be solved trivially



Law of recursion

1. Must have a base case
2. Must change its state and move toward the base case
3. Call itself recursively



Fibonacci sequence: [0, 1, 1, 2, 3, 5, 8, 13, 21, 34]

	Recursion	Iteration
Definition	Recursion is when a function calls itself repeatedly	An iteration is when a loop is repeatedly executed until a certain condition is met
Time complexity	High	(Relatively) Low
Memory	High memory occupation	Low memory occupation
Overhead	There is an extensive overhead due to the repetitive calls of the function	There is no overhead in iteration
Usage	Produces short code. In many case is more comprehensible and similar to the way in which we will solve the problem	Long code, potentially difficult to write. Useful when we have to balance the time complexity against a large code size

NOTE: It is always possible to convert an iterative solution into a recursive solution and vice versa

SEARCH AND SORT

-- search methods --

Sequential (or linear) search

Easiest searching algorithm. Check each element one by one

Binary search

ONLY FOR ORDERED LIST

Divide and conquer strategy

	Number steps	Computing time	Worst case
Item is present	O(1)	O(log n)	O(log n)
Item is not present	O(log n)	O(log n)	O(log n)

Hashing

Hash function: mapping between an item and the slot where that item belongs. Simple one is remainder between the item and the size of the table

h(item) = item % len(table)

Perfect hash table => no collision (almost impossible in real scenarios). Are efficient (O(1)) only when the number of entries is large

Dinctionary are the build-in implementation of hash table in Python.

-- sorting methods --

Bubble sort

Computational complexity O(n^2)

Simplest and less efficient sorting algorithms

Adjacent items are compared and swapped if they are out of order. After the first pass the largest element is in the correct position.

Each pass place the next largest value in place

Selection sort

Computational complexity O(n^2) but faster then bubble sort

Similar to bubble sort but it make only one exchange for every pass

With each interaction you select the biggest that has not yet being sorted
When passing the list we look for the largest value, after completing the pas place the largest value in the proper location

Insertion sort

Computational complexity O(n^2) but faster then selection and bubble sort

The algorithm maintains a sorted sub-list in the lower positions of the list

The algorithm maintains a sorted sub-list in the lower position of the list. Each new item is inserted into the sub-list as:

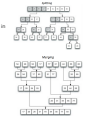
- Items in the sorted sub-list that are greater than the current item are shifted one position to the right.
- When we reach a smaller item or the end of the sub-list the new item can be inserted

Merge sort (recursive)

Computational complexity O(n log n), better then bubble, selection and insertion

Divide and conquer strategy. Works recursively by dividing the list to be sorted in half

- If the list is empty or has one item, it is sorted (**base case**)
- If the list has more than one item, the algorithm splits the list in half and recursively invoke a merge sort on both halves
- Once the two halves are sorted, the **merging** is performed
- **Merging** consists in taking two smaller sorted lists and combining them together into a single sorted new lists



Quick sort (recursive)

- Select a value in the list called **pivot**
- Apply the **partition** process
  - Rearrange the list until the pivot reach a position (**split point**) in which all the elements less than the pivot will be at its left and all the elements greater that the pivot will be at its right
  - Split the list at the split point to obtain two smaller sub-lists
- Recursively call the previous steps to sort the sub-lists

When rightmark < leftmark: change the pivot value with the rightmark

TREES

↔ Binary tree ↔

A node can have at most two children (left and right child)

Full Binary tree

Perfect Binary tree

Complete Binary tree

Tree Traversal

Preorder

Visit the root, then the left subtree, then the right subtree

Inorder

Visit the left subtree, then the root, then the right subtree (sorted for BST)

Postorder

Visit the left subtree, then the right subtree, then the root (children before parent)

Use in code (breadth-first):
Queue (FIFO) data structure

Binary Heap

- A binary heap is a...
- Complete binary tree (every level, except possibly the last, is completely filled, and all nodes in the last level are as far left as possible)
- Implemented using an array
- Used in **Heap Sort** and for fast min/max operations (like in Dijkstra's algorithm)

They are the implementation behind a priority queue (the data coming out first has the highest priority). Use cases include: sorting algorithms (heap sort), graph algorithms (Dijkstra's algorithm), and priority queues.

Min (or max) heapify

Process of rearranging elements in a binary heap to maintain the heap property

Local fix-up (O(log n)):
- Compare the node to its children
- Swap with the smaller child (for min-heap) or larger child (for max-heap)
- Repeat until the heap property is restored

Insert a new element into heap

1. Add the new element at the end of the tree (left-most free spot).
2. Compare the new element with its parent node.
3. If the new element is smaller than its parent (for a min-heap), swap them.
4. Repeat steps 2 and 3 until the heap property is restored or the element becomes the root.

Remove (for min) Heapify

1. Remove the root node (the minimum value in a min-heap).
2. Move the last element in the heap to the root position.
3. Perform a "heapify down" operation to restore the heap property:
   - Compare the new root with its children.
   - If the root is greater than either of its children, swap it with the smaller child.
   - Repeat this process with the swapped child until the heap property is restored or the element becomes a leaf node.

Binary Search Tree (BST)

- Every node's left subtree contains only values less than the node's value
- Every node's right subtree contains only values greater than the node's value
- Both left and right subtrees are also binary search trees

- Used in many data structures, including sets and maps
- Allows for efficient searching, insertion, and deletion operations

Add a node

Using a left or a right child?

See if it is in tree

1. Create a node

1. Create a node (the key, value, and left and right children are null)
2. Set the key and value to the ones we want

2. Find a node

3. Create a node with 1 child

4. Create a node with 2 children

We need search among the children the node that will be the parent of the node we want to remove. To find this among left and right subtree

We need to find the **successor** (or **predecessor**) of the node we want to remove

If the right child of the node to be removed is the left child, we remove it and put the left child as

If the right child of the node to be removed is not the left child, we remove it and put the right child as

Self-Balancing Search Trees

Binary trees can become inefficient if they are not balanced. For example, if you insert values in ascending order, you end up with a linked list. Self-balancing trees solve this issue.

AVL Trees

Adelson-Velsky and Landis (the inventors of it) was the first balanced binary tree to be invented.

Every node has a **balance factor** (height of left subtree - height of right subtree).

Balance factor must be **-1, 0, or 1**. If it becomes -2 or 2, the tree rebalances itself.

Left-Left Case (BF = 2, 1)

- Imagine the root node has a left child and the left child has a left child as well (a "left-left" chain).
- This causes the tree to become unbalanced, with the root node having a balance factor of 2.
- To fix this, we perform a single right rotation around the root node.
- After the rotation, the left child becomes the new root node, and the original root node becomes the right child of the new root node.

Right-Right Case (BF = -2, -1)

- Imagine the root node has a right child and the right child has a right child as well (a "right-right" chain).
- This causes the tree to become unbalanced, with the root node having a balance factor of -2.
- To fix this, we perform a single left rotation around the root node.
- After the rotation, the right child becomes the new root node, and the original root node becomes the left child of the new root node.

Left-Right Case (BF = 2, -1)

- Imagine the root node has a left child, but the left child has a right child (a "left-right" chain).
- This causes the tree to become unbalanced, with the root node having a balance factor of 2.
- To fix this, we perform a double rotation: first a left rotation around the left child, then a right rotation around the root node.
- After the rotations, the right child of the original left child becomes the new root node, and the original root node becomes the left child of the new root node.

Right-Left Case (BF = -2, 1)

- Imagine the root node has a right child, but the right child has a left child (a "right-left" chain).
- This causes the tree to become unbalanced, with the root node having a balance factor of -2.
- To fix this, we perform a double rotation: first a right rotation around the right child, then a left rotation around the root node.
- After the rotations, the left child of the original right child becomes the new root node, and the original root node becomes the right child of the new root node.

Red-Black Trees

Self-balancing binary tree data structure where each node has an extra attribute, a color, either red or black. In addition to the ordinary requirements imposed on binary search trees, the following properties must hold:

Properties

1. Each node is either red or black.
2. The root and leaves (NIL nodes) are black. If a node does not have a child, then the child field contains a special NIL node.
3. All children of a red node are black. In other words, no two red nodes can be adjacent to each other; however, two black nodes can be adjacent.
4. For each node, all simple paths from the node to descendant leaves contain the same number of black nodes (sometimes referred to as the black-height of the node).

GRAPH

Operations of Graph ADT

Operation	Effect
Graph()	Creates a new empty graph
addVertex(vert)	Adds an instance of Vertex to the graph.
addEdge(fromVert, toVert)	Adds a new, directed edge to the graph that connects two vertices
addEdge(fromVert, toVert, weight)	Adds a new, weighted, directed edge to the graph that connects two vertices.
getVertex(vertKey)	Finds the vertex in the graph named *vertKey*
getVertices	Returns the list of all vertices in the graph
in	Returns *True* if the given vertex is in the graph, *False* otherwise

-- How to implement a graph --

	Adjacency Matrix	Adjacency List
Space complexity	$O(|V|^2)$	$O(|V|+|E|)$
Add a vertex	$O(|V|^2)$	$O(1)$
Remove a vertex	$O(|V|^2)$	$O(|E|)$
Add an edge	$O(1)$	$O(1)$
Remove an edge	$O(1)$	$O(|V|)$
Check if two vertices are adjacent	$O(1)$	$O(|V|)$
Usage	Good for dense graph	Good for sparse graph

Adjacency matrix

Each row and columns represents a vertex, the value in the cell indicate the weight. If no wait is empty or 0 (aka no edge). When two vertices are connected by an edge we say that they are adjacent

Pros
- Easy to read
- Good representation for dense graphs (lots of edges/connections)
- O(1) time for adding/removing an edge and to verify existence

Cons
- High memory usage O(V^2)
- Very inefficient representation for graph with few edges/connections
- Adding or removing a vertex requires O(V^2) time

Adjacency list

We keep a master list of all the vertices in a graph object
Each vertex object in the graph maintains a list of the other vertices that it is connected to (plus the weight if present)

Pros
- Memory efficient, O(|V| + |E|) space complexity
- Good for representing sparse graphs
- O(1) time for adding a vertex or an edge

Cons
- Not efficient for dense graph
- Removing an edge or verify if it exists requires O(|V|) time

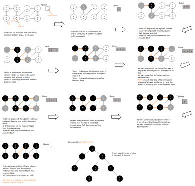
-- Breadth First Search (BFS) --

FROM ONE SOURCE TO ALL DESTINATIONS (for unweighted graphs)

- BFS finds all the vertices that are at distance k from s before it finds any vertices that are at distance k+1
- It computes the **shortest path** (smallest number of edges) from s to each reachable vertex
- It produces a **breadth first tree** with root s that contains all the reachable vertices

BFS use a Queue to decide which vertex to explore next

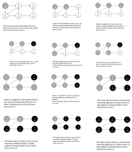
Colors
- **WHITE**: not yet discovered (each vertex is initialized as white)
- **GRAY**: discovered (aka visited for the first time) but not yet explored. Each adjacent vertices can be both white or black
- **BLACK**: completely explored (no adjacent white vertices)



-- Depth First Search (DFS) --

Explore the graph as deeply as possible along each branch before backtracking
- When DFS reaches a vertex, it marks it as visited, then moves to an adjacent unmarked vertex and continues recursively until there are no more adjacent unmarked vertexes
- DFS backtracks and check different edges for finding other unmarked nodes following the same recursive procedure
- The process continues until all the vertexes have been visited

DFS keeps track of two timestamps for each vertex
- **Discovery time**: records the number of steps in the algorithm before a vertex is first encountered
- **Finish time**: record the number of steps in the algorithm before a vertex is fully explored



-- Topological sorting --

Takes Direct Acyclic Graph (DAG) and produces a linear ordering of all its vertices.

On the same graph multiple topological sorts are possible but the first vertex must always be a vertex with no incoming edges

Procedure
1. Run DFS to compute the finish times for each vertex
2. Store the vertices in stack in decreasing order of finish time
3. Return the stack and pop all the elements to obtain the result of the topological sort

Example: how to make pancakes

-- Strongly connected components --

Strongly connected

Every vertex is reachable by any other vertex (exist a path from each vertex to each other vertex in the graph)

Strongly connected component of a direct graph G is a sub-graph of G that is strongly connected

-- Kosaraju's algorithm --

1. Run DFS on the graph G to compute the finishing time of each vertex
2. Compute the graph G^t the transposition of G (reverse the direction of all edges)
3. Run DFS on G^t but consider the vertexes in order of decreasing finishing time as computed in step 1
4. Each tree in the forest computed in step 3 is a strongly connected component

-- Minimum spanning tree --

Given an undirected graph a **spanning tree** is a acyclic subgraph that connects all the vertices of the graph. (A graph can have multiple spanning tree)

Minimum spanning tree: spanning tree in which the sum of all the edge weights is minimized

-- Shortest Path --

Shortest path: from a vertex u to a vertex v is a path in which the sum of the weight of its constituent edges is minimized

-- Prim's algorithm --

Used to compute the minimum spanning tree of a graph. A **Greedy algorithm** (at each step it adds to the tree the safe edge with the lowest weight)

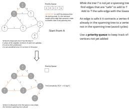
Start from a node and add it to the visited list. Then add the node that have the lowest weight, and keep repeating (chooses the smallest from all the visited notes) until all the nodes are all visited/connected

While the tree T is not yet a spanning tree:
find edges that are "safe" to add to T
Add to T the safe edge with the lowest weight

An edge is safe it it connects a vertex that is already in the spanning tree to a vertex that is not in the spanning tree (avoid cycles)

Use a **priority queue** to keep track of the vertices not yet added

Start from A



- Both Prim's and Dijkstra's algorithms derive from Breadth First Search
- Prim's algorithm works with both positive and negative weights, while Dijkstra's work only with positive ones
  - NOTE: to get the shortest path in a graph with both positive and negative weights use the Bellman-Ford's algorithm
- Dijkstra's works with both directed and undirected graphs, while Prim's works only with undirected ones
- Both the algorithms are greedy, but they minimize different things:
  - Prim's algorithm minimizes the total weight of the spanning tree
  - Dijkstra's algorithm minimizes the path from a source to a destination
- If it reaches all nodes, also Dijkstra's creates a spanning tree, but it is not guarantees that it is a minimum spanning tree

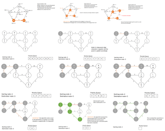
-- Dijkstra's algorithm --

FROM ONE SOURCE TO ALL DESTINATIONS (for weighted graphs without negative weights)

Provides shortest path from a starting vertex to all other reachable vertices on a weighted graph.
Commonly used to find the shortest path from a vertex A to a vertex B

Is a **greedy algorithm** since at each step it chooses the path with lower distance from the source

Work similar to Breadth First Search (BFS) keeping track of the distance of each vertex from the starting vertex s
- In BFS the distance of a vertex is the **minimum number of edges from s**
- In Dijkstra the distance of a vertex is the **total weight of the smallest weighted path from s**



-- A* search algorithm --

FROM ONE SOURCE TO ONE DESTINATION (for weighted and unweighted graphs)

Extension of Dijkstra's algorithm that uses a heuristic to efficiently find the shortest path from a source to a destination in a graph. Is **Optimally efficient**: there is no other optimal algorithm that is guaranteed to expand fewer nodes than A*

- At each iteration Dijkstra choose the path with the lowest cost from the source node
- At each iteration A* selects the path that minimizes the following equation $f(n) = g(n) + h(n)$
  - n is a possible next node on the path
  - g(n) is the cost of the path from the starting node to n
  - h(n) is a heuristic function that estimates the cost from n to the destination node

Heuristic function is problem specific. There is no function optimal in all the cases
Exact heuristic: function that returns for each node its exact distance to the destination. Extremally time consuming, approximation are generally food and faster than Dijkstra's algorithm

Will find the shortest path only if the heuristic function is **admissible**, an overestimated (non-admissible) heuristic can lead to find suboptimal paths and do unnecessary exploration
